

Tytler's Leaf Warbler *Phylloscopus tytleri*: non-breeding distribution, morphological discrimination, and ageing

PAMELA C. RASMUSSEN

A review of specimens of Tytler's Leaf Warbler *Phylloscopus tytleri* taken outside the breeding season established that the species is a regular fall transient through the Himalayas of Himachal Pradesh, wintering in the Western Ghats and Nilgiris. The route taken in spring appears to be somewhat more easterly, with scattered records both to the north and south of the Satpura Range and in the Himalayas of Uttar Pradesh and Nepal. In addition, a re-examination of the evidence of breeding east of the known range shows it to be suggestive but inconclusive. A *P. tytleri* specimen purported to have been taken in the Uttar Pradesh Himalayas in November by Meinertzhagen is almost certainly a missing late September or early October specimen collected in Simla by Davison. The only specimen record of the species from Orissa was found to be a misidentified Greenish Warbler *P. trochiloides*. Specimen-based identification criteria are summarized, and it is shown that lengths of the nasal groove and rictal bristles are diagnostic of *P. tytleri*. Aging of specimens based on a combination of rectrix shape and cranial and tarsal ossification visualized in x-rays shows that first-winter and fresh fall adults are not distinguishable in the field. During spring but not at other seasons, *P. tytleri* often has reddish, tiny-grained pollen adhering to the feathers of its forehead.

INTRODUCTION

Tytler's Leaf Warbler *Phylloscopus tytleri* Brooks 1871 is a small, drab, near-threatened (Collar *et al.* 1994) warbler that breeds only in a very limited area of the Western Himalayas from north-eastern Afghanistan (Paludan 1959) east at least through Kashmir (Ali and Ripley 1983). Although adults of *P. tytleri* possess distinctively shaped bills (Plate 1), this is often not obvious and the species poses significant identification problems, as evidenced by the frequency of documentable misidentifications (detailed below). At all seasons it occurs alongside several more abundant congeners, and although on its breeding grounds *P. tytleri* is locally common and has been relatively well-studied (Price and Jamdar 1990, Price 1991, Richman and Price 1992, Marchetti *et al.* 1995), its migratory and wintering range remains poorly documented owing to the wide dispersal of what must be a relatively small world population and the difficulty of certain identification. The purpose of this paper is to summarize critically evaluated specimen records of this near-endemic, little-known species's occurrence primarily outside its known breeding range, and to clarify its identification and aging to facilitate future study of its distribution and biology.

METHODS

Specimens examined

During the course of this study I examined nearly all known specimens of *P. tytleri*, as well as series of similar congeners at the American Museum of Natural History (AMNH), Academy of Natural Sciences of Philadelphia, The Natural History Museum (BMNH), Bombay

Natural History Society (BNHS), Carnegie Museum of Natural History, Field Museum of Natural History (FMNH), Los Angeles County Museum (LACM), Michigan State University Museum (MSU), Museum of Comparative Zoology (MCZ), National Museum of Natural History (USNM), Yale Peabody Museum, University of Michigan Museum of Zoology (UMMZ), and Zoological Survey of India, without finding additional misidentified non-breeding specimens of *Phylloscopus tytleri* beyond those mentioned below. Computer catalogues examined for all other North American museums with significant holdings of Indian bird specimens list no additional specimens of this species.

Measurements

'Culmen (ff)' was measured from the distal edge of feathers; 'culmen (fs)' from skull; 'wing' is maximum length (flattened and straightened); 'tail' is from insertion point between central rectrices; 'tail/wing ratio' is given as in Ticehurst (1938). 'Nasal groove' is from the distal edge of the feathering to the distal end of the groove in which the nostril is located; 'rictal bristle' is the length of the longest bristle found on either side; 'bill depth' is the depth of the upper mandible at the edge of the feathering. All measurements were taken by the author except those of one AMNH specimen taken by M. LeCroy and one UMMZ specimen by J. Hinshaw. Original measurements are available from the author upon request.

Ageing

To determine whether first autumn *P. tytleri* can be distinguished from fresh-plumaged fall adults, I examined shape of rectrices, presence of growth bars,

and radiographs (x-rays) for degrees of skull and tarsal ossification. X-rays taken by the author included ventral, lateral, and ventrolateral views of 16 specimens from North American museums in the laboratory of the Division of Fishes, National Museum of Natural History (NMNH), using Kodak Industrex-M and SR film, at 25 and 30 kV and 5 mA for 30 sec; x-rays of 19 BMNH specimens were made by R. P. Prys-Jones and P.C.R. using a Solus-Schall at 30 kV and 10 mA for an exposure of 40 sec, in the laboratory of the Lower Vertebrate Curation Group, Department of Zoology, The Natural History Museum, BMNH. Specimens were compared on the same x-rays to avoid differing effects due to varying exposures and developing protocols. The opacity and/or granularity caused by preservative and various stuffing materials on the appearance of the skull in x-rays of some specimens was distinguished from indicators of ossification, and no age determination was made in a few cases in which it proved impossible to confidently visualize skull pneumatization.

Specimen authentication

I attempted to determine the likelihood of authenticity of three *P. tytlteri* specimens of questionable provenance, two of which potentially form significant records of this species, by comparing the specimens with those of other series in external appearance and by examination of x-rays. First, doubt was cast upon the validity of data accompanying a specimen (BMNH 1965.M.14256) purported to have been collected in early November at about 2,300m in the Himalayas of Uttar Pradesh by Richard Meinertzhagen, based on recent findings of widespread specimen fraud in the Meinertzhagen Collection (Knox 1994, B.O.U. 1997, Rasmussen and Collar in press, Rasmussen and Prys-Jones in prep.). To determine whether the label data could be genuine I compared Meinertzhagen's specimen in detail with those it most closely resembled in the BMNH collection: series by H. Whistler, A. E. Jones, and W. Davison. The specimen registers for these collections at the BMNH as well as that for the Jones acquisition at the BNHS were examined for the possible listing of specimens missing from the collections. Another Meinertzhagen specimen at the Berlin Museum was compared with the above for external preparation style.

The third problematical specimen (ROM 66799) bears the label annotation: [Mahabaleshwar...], 'Locality deduced, see collector's nos. 1-24 of this lot'; this specimen was thus compared both externally and on x-ray with two BMNH *P. tytlteri* specimens collected at Mahabaleshwar by Fairbank, and with seven specimens of other passerine taxa from Mahabaleshwar and nearby Sirur from the collection of S. A. Winsor, and now in the Field Museum of Natural History (FMNH), to evaluate possible style similarities. X-rays for the Winsor specimens were done by K. Swagel at the FMNH.

Pollen

The presence or absence of reddish pollen on the feathers of the head was noted for each *P. tytlteri* specimen examined. Occasionally it was difficult to distinguish between bloodstained feathers and pollen, and this was noted in such cases. Usually, however, the pollen was readily seen as a reddish sticky substance on the forehead and sometimes the chin, often partially gluing the

feathers together. This was verified to be pollen by J. Kress, Department of Botany, National Museum of Natural History, who examined the pollen *in situ* on detached feathers of USNM 536237 under light and scanning microscopes.

BREEDING DISTRIBUTION OF *P. TYTLTERI*

The known breeding range of *P. tytlteri* encompasses a small, presumably relictual (Martens 1980) area in the Western Himalayas (Figure 1), including Nuristan, extreme northeast Afghanistan (Paludan 1959; specimen from the Zoologisk Museum, University of Copenhagen, ZMUC 1.12.1951.1195, reexamined for this study); Kaghan Valley, N.W.F.P. (an uncatalogued egg set in BMNH) (Whitehead 1914); north to Gilgit (Biddulph 1881, 1882); and east through Kashmir (Richmond 1895, Bates and Lowther 1952, Brooks 1872b, Davidson 1898, Osmaston 1923, 1926, 1927 and 1930, Price and Jamdar 1990) to the Zoji La Pass (Stoliczka 1874), Baltal, and Kargil, western Ladakh (Sharpe 1891, Vaurie 1972). There are numerous sight reports, although no specimens were traced, of the species in summer from much of the intervening area between Nuristan and Gilgit and Kaghan Valley, but none yet from Chitral (Roberts 1992).

Statements that *P. tytlteri* breeds in Uttar Pradesh east to Garhwal or Kumaon (Hartert 1910, Baker 1924 and 1933, Jones 1948) have long been discounted, as their basis was unknown to Ticehurst (1938), and subsequent ornithological work in those regions has failed to substantiate the claims. However, an egg set attributed to this species from Garhwal in the BMNH collections must certainly be the basis for the assertions, and the collector of the egg set (S. L. Whymper) seems to have been reliable (M. P. Walters, verbally 1996). The eggs, collected on 27 June 1907, are pure white and the measurements are consistent with those of *P. tytlteri*. Baker's accompanying card reads 'Taken by S. L. Whymper and sold to me with the rest of his collection. Data copied from top of chip box in which the eggs were packed.' However, the fact that Whymper himself apparently did not publish upon these eggs in his several subsequent papers on the breeding of birds in Garhwal (Whymper 1907, 1910, 1911, 1915) in which a number of species of *Phylloscopus* are featured, suggests uncertainty as to the provenance and/or identity of the eggs. The locality of the only *P. tytlteri* egg set from Kishtwar in the BMNH (also unregistered) may also be questionable, as the label bears the annotation 'I think these were taken in our expedition to Ladak, I could probably tell by Spec. 484 when I get back to town'. Because of previously documented problems with the Baker Collection (Harrison 1966, Harrison and Parker 1966a and b, 1967, Parker 1970), Baker's nidification records can only stand when corroborated by more reliable records.

A previously unpublished specimen in very worn plumage (Field Museum of Natural History, FMNH 241166) was collected by W. N. Koelz on 4 July 1936 at Kukti, Chamba District, western Himachal Pradesh. However, fledging has been recorded on 19 July (Price and Jamdar 1990), and juveniles have been collected

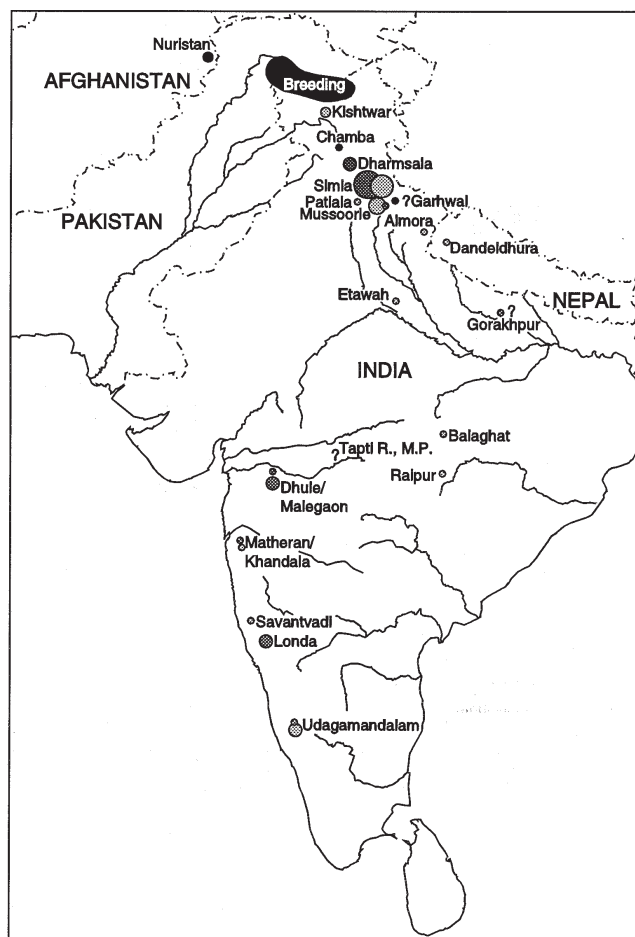

Figure 1. Map of localities from which specimens of *P. tyleri* are known. Specimens from the main portion of the breeding range are not mapped individually. Specimens from Keonthal and Koti State are included with Simla. Circle size is roughly proportional to the number of specimens available from each locality; black-filled shapes are specimens from the summer months (June–August); dark grey-shaded circles from autumn (September–November); medium grey-shaded circles from winter (December–February); and light grey circles from spring (March–May). Full data from each specimen available in Table 1.

on 2 and 4 August (Kashmir); 9 August (Gilgit), and 11 August (Sonamarg). In late summer, *P. tyleri* remains on or near its breeding grounds, often in family parties above the timberline (T. D. Price, *in litt.* 1996). Some remain well into September (Gulmarg, 13 September, BMNH 1926.7.1.138; Palgahm 20 September, MCZ 149572), where they undergo a complete moult before migration (Williamson 1962). Thus, 4 July seems unusually early for a bird, especially one which has not yet moulted, to be far from its breeding grounds, and though it remains to be proven, the FMNH specimen suggests that *P. tyleri* may breed in Chamba District of Himachal Pradesh, to the south-east of its definitely known breeding range. The species was not found in summer around Manali, just to the east of Chamba, despite two summer's field work on *Phylloscopus* species there (T. D. Price, *in litt.* 1996).

Price and Jamdar (1992) have previously shown that Alexander's (1950) discussion of the Plain Leaf Warbler, *P. neglectus*, in Kashmir actually refers to *P. tyleri*. In

addition, the same should be said for the discussion of *P. neglectus* in Alexander (1969), and thus observations referred by him to *P. 'tyleri'* in Kashmir most likely refer to yet another species of *Phylloscopus*.

RANGE IN MIGRATION

P. tyleri has not been recorded in the plains of Pakistan (Ticehurst 1926, Roberts 1992) or the arid regions of north-western India, despite the fact that these areas lie across the most direct route between the breeding and wintering grounds for the majority of the population. Specimen records (Figure 1) confirm Ticehurst's (1926) suggestion that *P. tyleri* takes an initially south-eastward, then south-westward route on its fall migration, and the reverse on spring migration, not a strictly north-south route (Vietinghoff-Scheel 1984). Though records are still few and further data are needed, it appears that to some extent spring migration follows a more easterly course than that taken in autumn; none of the specimen records east of Mussoorie is from the fall (Figure 1).

A single previously unpublished specimen (BMNH 1965.M.14256) purportedly taken in Chakrata, extreme western Uttar Pradesh, on 5 Nov. 1912, by Col. R. Meinertzhagen, represents the only fall *P. tyleri* specimen traced for the species in the Himalayas or the Siwaliks from after 14 October. Although, admittedly, no other November specimens are known for the species, this seems a late date for this long-distance migrant to still be in the mountains at an elevation of c. 7000'. [Another specimen that Meinertzhagen exchanged to the Museum für Tierkunde, Berlin (ZMB 26.269), labelled by him as being from Srinagar, Kashmir, at 5500', on 12 September 1925, but not listed in his catalogue (R. P. Prys-Jones *in litt.* 1998), does not conflict with the species's known range and is suspect only because of its preparation style.] No confidence can be placed in the authenticity of Meinertzhagen's specimen records without careful evaluation (Rasmussen and Collar *in press*, Rasmussen and Prys-Jones *in prep.*), and his Chakrata *P. tyleri* specimen is virtually identical in preparation style and its very fresh plumage to that of five fall specimens collected in Simla by W. Davison. In particular it is strikingly similar to BMNH 1886.7.8.834, collected there by Davison on 14 October 1880, and only slightly less so to BMNH 1886.7.8.833, from 3 October 1880; on x-ray view each of these specimens show a characteristic short support stick wrapped for much of its length with x-ray translucent stuffing material. The Berlin specimen was not x-rayed but agrees in all external details with the Davison Simla series as well. The BMNH register lists seven Davison specimens from Simla in this series, but only five so labeled can now be found. The two missing specimens are: BMNH 86.7.8.830, female, 23 September 1880; and BMNH 86.7.8.832, male, 1 October 1880. The 'Chakrata' specimen is less similar both externally and on x-ray views to specimens collected by Whistler ($n = 6$ x-rayed) and Jones ($n = 6$), and no BMNH-registered specimens from the Whistler Collection (which includes Whistler's and some of Jones's specimens) are now missing from the BMNH collection, nor were any of Jones's specimens listed in the BNHS log of his accession missing from that collection in December 1996. In addition, the

*Doubt exists for these records; see text.

'Chakrata' specimen does not closely resemble in style that of numerous other specimens supposedly obtained there by Meinertzhagen during the same time period, and currently under study (Rasmussen and Prys-Jones in prep.). Based on this and strong evidence of many other specimens with falsified data in the Meinertzhagen collection, I consider that both Meinertzhagen specimens were in fact collected in Simla, one in late September and the other in early October by Davison, so neither record is included in the map.

Five *P. tyleri* specimens that were presumably on migration through the Mussoorie area of northwestern Uttar Pradesh were examined (Figure 1, Table 1). These are MSU 5997 and 5986 (collected 3 October and 20 March 1965 respectively, by R. L. Fleming, Jr.); University of Kansas Museum of Natural History (KUMNH) 71186 and 71187 (previously identified as Common Chiffchaffs *Phylloscopus collybita*; both collected 27 March 1973 by R. C. Waltner); and USNM 536237 (previously identified as a Greenish Warbler *Phylloscopus trochiloides*, collected 30 March 1968 by J. Jantzen). These previously unpublished spring records suggest that *P. tyleri* may be regular in the Mussoorie area in the spring, although it was listed as 'occasional' in spring by Fleming (1968). Fleming listed the species as a common fall transient ('arriving by late September') in the region, but only one fall specimen from Mussoorie (that collected by Fleming) has been located; this is the easternmost fall specimen available.

A record of *P. tyleri* collected at Gorakhpur, northeastern Uttar Pradesh by Mr. Hope Simpson (Osmaston 1913; Figure 1), is the north-easternmost for the species, and it is also the only non-spring record east of Mussoorie. This record has not been cited in recent treatments except Vietinghoff-Scheel (1984), and A. E. Osmaston's (1913) statement that *P. tyleri* was 'an uncommon bird' there seems surprising for a species so far from its known range, and so far to the north in February. Although Whistler and Kinnear (1935) stated that a Gorakhpur specimen published by Osmaston (1913) as *Caprimulgus maharattensis* (but that actually was a juvenile *C. monticolus*) 'is in [Whistler's] collection together with the rest of A. E. Osmaston's skins', implying that the *P. tyleri* in question would be included, there is no indication in the BMNH register of Whistler's collection of a *Phylloscopus* specimen of any species with the appropriate date and locality information (R. P. Prys-Jones, *in litt.*), and despite considerable effort no *P. tyleri* specimen from Gorakhpur could be traced for the present study. Because of the above, it is possible that the Gorakhpur record may represent a misidentification and it is here considered to require verification.

Ali and Ripley (1983) list passage records from '... Khandesh, M.P. and U.P. (Etawah)...', but here it should be clarified that Khandesh is in Maharashtra, and the 'M.P.' almost certainly refers to a record from Central Provinces (Ticehurst 1938) which was presumably based on a Raipur specimen (BMNH 98.12.12.717) collected by W. T. Blanford on 14 March 1870, the label of which bears the annotation 'originally identified as *viridanus*' [*P. trochiloides viridanus*], but with no indication as to when or by whom it was reidentified. A record mentioned by Ripley (1978) for the Tapti River in Madhya Pradesh (M.P.) could not be traced in this study, and M.P. may be a lapsus for Maharashtra. An

overlooked specimen of *P. tyleri* (previously identified as *P. collybita tristis*) from central India was located in the collections of the Los Angeles County Museum: LACM 33031, a male collected by M. A. Machris on 19 March 1959, at Lougur, Balaghat Forest Division, Madhya Pradesh (ca. 22°N 80°E). Thus there are now at least two valid records from Madhya Pradesh, suggesting that the species may be at least an occasional, if not regular, spring migrant through the Satpura Range and other low hills of central India.

WINTER RANGE OF *P. TYTLERI*

Specimen records of presumed wintering *P. tyleri* are mapped in Figure 1, with fuller detail presented in Table 1. There appears to be no basis for the unreferenced, erroneous statement by Sibley and Monroe (1990, uncorrected in Sibley and Monroe 1993) that *P. tyleri* winters in Myanmar (Burma); there appear to be no actual records for the country, and the species is not listed in Smythies (1986 and earlier editions). Vietinghoff-Scheel's (1984) mention of *P. tyleri* in the Eastern Ghats is actually in reference to specimens from the Nilgiris; no authentic Eastern Ghats records are known; this error probably arose from the title of the paper in which the Nilgiris records are mentioned (Whistler and Kinnear 1933).

A *P. tyleri* specimen lacking an original label from the Royal Ontario Museum (ROM 66799, previously identified as '*Urosphena p. pallidipes*; *Acanthopneuste*') lacks definite data but was deduced by an unknown person and for unknown reasons to come from Mahabaleshwar, as discussed above. It was received as part of an exchange from Queen's University Museum of Biology, and no further information was available (B. Millen, *in litt.* 1996). This specimen is in very bright fresh plumage and is a full adult, showing broad rectrices and a completely ossified cranium in a radiograph. Although of unknown date, in plumage it is consistent only with an early fall adult. Questions are raised about the 'Mahabaleshwar' locality of this specimen by the fact that a few other ROM specimens (such as *Ammoperdix griseogularis*) with the same deduced locality are most unlikely to have originated at Mahabaleshwar except through trade or as part of a collection assembled there from various localities, based on their known distribution and habitat requirements. In preparation style it does not match specimens of other collectors of non-breeding individuals of this species, including either externally or, on x-rays, that of two *P. tyleri* specimens collected by Fairbank not far from Mahabaleshwar (Savantvadi and Khandala) in March and April, but originally misidentified as *P. viridanus* and thus not mentioned in Fairbank's (1876) account of the region's avifauna. However, both externally and internally, the 'Mahabaleshwar' specimen is similar in preparation style to several specimens of other passerine taxa now at FMNH, from the Winsor collection, collected at Sirur (18°50'N 74°23'E, c. 100 miles from Mahabaleshwar) (FMNH 19471–19474, *Saxicoloides fulicata*; FMNH 19475, *Monticola solitaria*) and from Mahabaleshwar (FMNH 19476–19477, *Turdus merula nigropileus*). The above Winsor specimens and the ROM specimen all share the following distinctive features: they have open

low belly incisions; their heads are tilted; they lack support sticks, or wound cotton or paper neck wands; most (including the ROM bird) have both legs lying together rather than crossed; they have a similar fine-grained x-ray opaque (presumably arsenic) preservative pattern on the inside of the skin; and the skulls have only a small hole cut at the base. The similarities between these specimens, especially the lack of any neck support, make it appear likely that the ROM *P. tytleri* was collected by Winsor, quite possibly at or near Mahabaleshwar as tentatively noted on the label.

Recently a specimen originally identified as *P. tytleri* (USNM 583081), which was collected by S. D. Ripley at Tikarpara, near the Mahanadi River, Dhenkanal District, Orissa on 17 February 1975, and the basis for the record of *P. tytleri* mentioned in Ripley (1978, 1982), was found to be a *P. trochiloides* (probably ssp. *viridanus*). The specimen, sexed as a probable male, shows an entirely pale lower mandible, recorded as 'dull orange' on the label; its bill is not as slender as is typical of *P. tytleri*; and it has an inconspicuous narrow, ill-defined whitish wingbar formed by narrow pale tips on the greater secondary coverts, all characters that differentiate *P. trochiloides* from *P. tytleri*. The measurements of USNM 583081 are: culmen (from skull) = 12.8 mm; wing (flattened and straightened) = 55.3; tarsus = 17.9 mm; tail (from insertion) = 42.7 mm. Slight damage to the base of the upper mandible gives the specimen a rather slender- and long-billed appearance that is atypical for *P. trochiloides*.

A *P. tytleri* specimen, purported to be the only one from Goa (Grubh and Ali 1976), was subsequently reidentified as *P. trochiloides* (Price 1980). However, Whistler and Ticehurst (MS), in a work in preparation prior to 1941, listed Goa as part of the range of *P. tytleri*, so there must have been an earlier Goa-collected specimen for which the present disposition is unknown. Another erroneous record of *P. tytleri* that has previously been corrected (Ticehurst 1938), but which has continued to be cited as valid, is Inglis's (1904) record from Tirhut, Bihar. The above-documented frequency of misidentifications of specimens of *P. tytleri* makes it very likely that additional specimens await correct identification among museum series of similar congeners.

SIGHT REPORTS

Sight records of *P. tytleri* away from its breeding grounds and presumably on migration include several western Nepal sightings in April (Inskipp and Inskipp 1991); one near Mussoorie on 28 March 1981 (P. Kaestner, unpubl. data); 30 specimen-supported observations at Mussoorie from 5–25 March and 'late Sept.' (Fleming 1968); two in Corbett, Uttar Pradesh on 21 March 1991 (P. Alström, *in litt.* 1996), and a 23 August sight record thought to be of this species on the Delhi Ridge (Gaston 1978) which is presumably the basis for the listing of Haryana in the species's range in Ripley (1982). These relatively eastern sight records of *P. tytleri* support the specimen-based hypothesis that the species takes a somewhat more easterly route in spring migration. *P. tytleri* was listed as 'seen regularly' at Rajaji National Park, north-western Uttar Pradesh (Pandey *et al.* 1994),

but was categorized as an 'altitudinal migrant' and a 'wintering' species there. This is almost certainly misleading terminology, presumably due to the status codes adopted in that paper; the species is otherwise (except for the clearly fraudulent Meinertzhagen specimen discussed above) known only as a migrant through that region, wintering much farther south (Figure 1). Hartert (1910) and Bates and Lowther (1952) also stated, without providing evidence, that some winter in the outer hills and adjacent plains. *P. tytleri* is listed by Abdulali and Panday (1978) as an 'uncommon passage migrant' from the Bharatpur/Agra area, presumably on the basis of a record of nine ringed at Bharatpur in 1970 (no date given) during the MAPS program (McClure and Porntip Leelavit 1972). Subsequently there has been one sight record, on 5 February 1987, from Bharatpur for which details were not provided (Jepson 1987). As no documentation appears to be available to support the ringing of so many *P. tytleri* specimens during one year at Bharatpur, where it has otherwise only been recorded once, and none of the ringed birds was reported as having been recaptured (McClure 1984), this record is highly questionable.

Winter sight reports of *P. tytleri* include a well-documented record of two seen near Munnar, Kerala (Harrap and Redman 1989, Neelakantan *et al.* 1993), a possible earlier record from the Nilgiris (Betts 1930), 'occasional' records from Wynaad, Kerala (Zacharias and Gaston 1993), three undocumented reports from Goa (Harris 1986), two from around Bombay (N. Jamdar, *in litt.* 1997, T. Price, *in litt.* 1998), and a report without details from Rajiv Gandhi (= Nagarhole) National Park, Karnataka (Lal *et al.* 1994). Additional sight records as noted on specimen labels and/or resultant publications, and validated by accompanying voucher specimens from the same locality, collector, and date, are summarized in Table 1. *P. tytleri* must certainly be to some extent overlooked on its winter quarters, but the fact that expert observers have not found it outside its breeding range despite special effort (B. King, P. Holt, K. Kazmierczak, verbally 1997) must be taken as an indication that either it occurs at a low density or very locally (the latter supported by the recent finding of extremely high densities in one locality in southern Maharashtra; T. Price *in litt.* 1998).

MORPHOLOGICAL DISCRIMINATION OF *P. TYTLERI*

Measurements of *P. tytleri* taken for this study are summarized in Table 2, and accord well with Ticehurst's (1938) four basic measurements (culmen from skull, tarsus, flattened wing, and tail) of both sexes combined. No sexual dimorphism was detected in these measurements (Table 2), although the correctness of sexing of individual specimens may be doubted. This is supported by the great preponderance of specimens sexed as males (27 males:11 females) that were obtained away from the breeding grounds. At least in fall and winter, both sexes would be expected to be more equally detectable and collectable, and fall adults and immatures with minute or obscure gonads are more likely to be missexed as males due to the superficial similarity of the adrenal glands to testes.

Plate 1. *P. tytleri* in Kashmir, May 1983 (photo courtesy U. Olsson; digitally enhanced and color-matched to spring specimens).

(Table 3, Figure 2). The long nasal groove is accentuated by the near lack of nasal tufts, which are prominent (on close inspection) on the other taxa. In direct comparison of birds in the hand, this difference can be clearly seen, but measurements are advisable. This measurement should be taken from the distal edge of the feathering at the bill base (not including rictal bristles) to the distal edge of the groove in which the nostrils are situated. While there was only minimal overlap between *P. tytleri* and similar species in nasal groove length (Table 3), other distinctive features should be taken into account as well when making an identification, especially in borderline cases. As the measurements in Table 3 were taken from dried specimens, they may be very slightly smaller than would be those of live birds. Note that in exceptional cases, missing or broken rictal bristles or loss of some feathers at the base of the bill of other species can emulate the features of *P. tytleri* to some extent.

Bill colour

The lower mandible is apparently never bright orange- or flesh-coloured in *P. tytleri* as in most *P. trochiloides viridanus* and *P. [t.] nitidus*, nor is it ever jet-black as in *P. collybita tristis*; usually the base of the lower mandible is slightly to clearly paler than the rest of the bill but of a dusky horn colour. Soft part notations on specimen labels include: 'bill blackish brown, base of lower m. horny'; 'apical half of l. m. blackish brown, rest of l. m. and gape yellowish'; 'bill horn, commissure dusky yellow'; 'bill dark brown, base of lower m. horny yellow'; 'l. m. pale brown, yellow at base and on edges along commissure'; 'bill dark horn, paler at base of l. m.'

Plumage of adults

The previous misidentifications of *P. trochiloides* as *P. tytleri* may have been partially due to the fact that worn

Figure 3. Specimens of *P. tytleri* (FMNH 241169, juvenile; MSU 5997, first-winter; FMNH 241171, ad. March; FMNH 241166, ad. July) showing the range of plumage variation.

or moulting *P. trochiloides* sometimes have the wingbars reduced or absent. Presence and conspicuousness of the wingbar in *P. trochiloides* is dependent upon molt schedule and wear (Price 1980), and dichotomous keys to the genus do not provide for *P. trochiloides* which have lost their wingbars (Ticehurst 1938; Williamson 1962; Ali and Ripley 1983). *P. tytleri*, which has two body molts

Figure 4. Radiographs of skin specimens of adult, first-winter, and juvenile *P. tyleri*, to show degrees of cranial and tarsometatarsal ossification. Left to right, FMNH 241169 (4 Aug. 1936, juvenile), MSU 5997 (3 Oct. 1965, first-fall), FMNH 241171 (1 Mar. 48, adult), FMNH 241170 (4 Aug. 1936, juvenile), ROM 66799 (no date, ad.).

a year (Ticehurst 1938), shows pronounced colour variation (Figure 3), and this no doubt contributes to the frequency of misidentifications and paucity of reliable records outside the breeding season.

First-fall and freshly moulted birds are brighter green above and have yellow-suffused underparts; some also show pale bases to the lower mandible. Most birds seen in passage both in fall and to a lesser extent early spring would show yellow-suffused lower underparts and supercilium, and fairly bright olive upperparts. The brightest individuals might be mistaken for its near relative (Richman and Price 1992), Tickell's Leaf Warbler, *Phylloscopus affinis*, which approaches *P. tyleri* in bill length and thinness (Price and Jamdar 1990), but *P. affinis* is almost uniformly fairly bright lemon-yellow below, including the throat which is apparently never yellow on *P. tyleri*.

Worn *P. tyleri* are considerably greyer above than they are in fresh plumage, and often lack any trace of yellowish below, sometimes even being dingy whitish on the lower underparts and with a greyish breast. These duller, greyer individuals invite confusion especially with *P. collybita tristis*, *P. [c.] sindianus*, and *P. neglectus*, but should be recognizable by the longer, paler-based bill, and much darker and more prominent eyestripe. *P. tyleri* on the breeding grounds in mid- to late summer shows the greatest degree of wear and drabest plumage, and just prior to the winter moult can also be quite dull-plumaged.

Adult *P. tyleri* may best be recognized in the field by the combination of mostly or entirely dark lower mandible; the rather long, uniformly slender, spike-like bill; olive upperparts; the rather short tail; the very long, prominent pale supercilium above a broad dark

eyestripe; and the lack of wingbar and pale tertial spots. While some *P. trochiloides* (especially the nominate race, with which *P. tyleri* does not normally overlap in range) may have a mostly dark lower mandible (Harrap and Redman 1989; Roberts 1992), probabilities are low that this character would be found in individuals of *P. trochiloides* for which the wingbar is also completely lacking on both sides, the bill is long and slender, and the tail is relatively short. Rarely, very worn Hume's Warblers *Phylloscopus humei* almost completely lose their pale tertial spots and/or wingbars (e.g., USNM 131117, 150435), being then very like worn *P. tyleri* except for the much shorter bill.

Juveniles

Juveniles are said to have slightly shorter bills (Inskipp and Inskipp 1991), which increases their resemblance to *P. trochiloides*. Of 13 adults and one first-winter specimen, mean bill length (from feathers) was 9.4 ± 0.55 mm, compared with five definite juveniles, for which mean bill length was 8.9 ± 0.19 . Sample sizes are too small for statistical analysis but these results appear to confirm that juveniles are shorter-billed. In addition, juveniles have noticeably browner breast sides than do adults, with virtually no yellow tinge on underparts; the upperparts are brownish-olive, greener on wing and tail edgings and with a slightly browner crown.

First-fall specimens

Analysis of x-rays of *P. tyleri* confirms that field identification of first-winter vs. adult individuals must normally be impossible, unless the birds are in the hand. Adults were distinguished on the x-rays by their double-layered skulls, visible on each side of the skull, and presence of bony struts visible as opaque dots over the entire roof of the cranium (Fig. 4). Figure 4 shows x-rays of the crania of one easily aged adult (right-most) and one first-fall specimen (second from left), while the other three specimens are difficult to age by cranial ossification due to their styles of preparation. This is due to the use of x-ray opaque preservatives, which also can result in a stippled pattern mimicking that of skull ossification; as well as the fact that the skulls are somewhat crushed in these specimens. In the juvenile specimens it can be seen that the proximal portion of the shaft of the tarsometatarsus is somewhat swollen in comparison with the other specimens; it does not appear possible to distinguish the first-fall bird from adults on this feature. The single first-fall bird (MSU 5997, Mussoorie, 3 October 1965, Fig. 4), which was definitely aged as such on the basis of its having a mostly unossified skull shown in x-rays and narrow rectrices, shows strongly yellow-washed lower underparts, grey-mottled breast, and a pale-based bill (Fig. 3), but is matched in all these features by some fresh fall adult specimens. For the small sample of fall specimens studied, rectrices were broad in two A. E. Jones specimens labeled adult by the preparator (BNHS 17362, 17367); narrow in one Jones specimen labeled 'juv by skull' (BMNH 17365); and broad in four of five Simla Davison specimens (including the Meinertzhagen specimen).

While growth bars could be seen on rectrices of some individuals, it could not be determined whether they matched up between rectrices, and so no conclusions were drawn as to age of specimens on that basis.

Pollen staining

Patches of reddish pollen can be seen adhering to the foreheads and sometimes also the chins of eight of nine March specimens; all ten April specimens; and four of eight May specimens. None of the specimens examined for other months had definite pollen on their heads. A sample of pollen analyzed proved to be extremely small-grained, and of an as yet unidentified species, but it is probably the same as that also found on some USNM *Prinia* specimens (J. Kress, verbally 1996). Pollen is frequently seen on netted *P. tytleri* in spring but not in the breeding season (Price and Jamdar 1991; T. D. Price *in litt.* 1995, 1996). Alexander (1969) saw *P. tytleri* feeding at a Flame of the Forest, *Butea monosperma* (Lam.) Kuntze, tree at Malegaon in the Surat Dangs in late February. In this case the warbler's identification was verified by three specimens collected by S. Ali and now at BNHS and MCZ, while the tree is of an introduced Malagasy species (J. Kress, verbally 1996). Pollen was not, however, seen on the Malegaon specimens known to have been feeding among flowers. N. Jamdar (*in litt.* 1997) has twice seen *P. tytleri* feeding on Flame of the Forest trees near Bombay. In an examination of all USNM specimens of the potential confusion *Phylloscopus* species listed in Table 1, none had obvious reddish pollen on their heads. Thus, the flower-probing habits of *P. tytleri* (shared with the dissimilar-looking Buff-barred Warbler, *Phylloscopus pulcher*; P. Alström, *in litt.* 1996; P. D. Round, photograph) may provide a supplementary clue to identification in spring, and on a close view in the field, reddish pollen may be visible on the forehead. The thin bill of *P. tytleri* is apparently related to the species's propensity for foraging by picking and probing in various substrates rather than flycatching (Price 1991, Richman and Price 1992, T. D. Price, *in litt.* 1995).

While some individuals of *P. tytleri* are fairly readily distinguished, others require considerably more care for reliable identification. Sight records of this plain but variable species, especially outside the known breeding grounds, should be carefully documented by notes, photographs, and recordings of any vocalizations (the latter are treated by Martens 1980, Harrap and Redman 1989, Roberts 1992). However, many sight records, even if carefully documented, cannot be taken as definitive. Netting records of birds outside the known breeding grounds or range extensions should be accompanied with full details, appropriate measurements (especially nostril groove length), close-up photographs showing bill structure and feathering at base of bill, and ideally, specimens to enable critical independent evaluation. Increased awareness of the identification criteria for *P. tytleri*, when rigorously applied, will eventually result in an improved understanding of the non-breeding range, behaviour, and ecology of this little-known, near-endemic, near-threatened species of the Indian subcontinent.

For information, specimen loans, and/or access to collections, thanks are due M. LeCroy, AMNH; R. Prys-Jones and M. P. Walters, BMNH; S. Unnithan, BNHS; D. Willard, FMNH; D. Beaver and L. Abraczinskas, MSU; R. A. Paynter, Jr., MCZ; S. Eck, Staatliches Museum für Tierkunde, Dresden (MTD); K. Garrett, LACM; S. L. Olson, G. R. Graves, and J. P. Angle, USNM; R. Prum and M. Robbins, KUMNH; B. Millen, ROM; R. B. Payne and J. Hinshaw, UMMZ; K. Roselaar, Zoologisch Museum, University of Amsterdam

(ZMA); S. Frahnert, ZMB; J. Fjeldså, ZMUC. Others who provided help and information include N. Rai, Pennsylvania State University; P. Kaestner, U. S. State Department; B. F. King; K. Kazmierczak; P. Holt; P. Alström; K. Winker, now of University of Alaska; T. D. Price and M. Katti, University of California at San Diego; N. Jamdar; R. L. Zusi, USNM. J. Kress, NMNH, examined pollen samples from feathers of *P. tytleri*. I thank U. Olsson for providing a photo of *P. tytleri*. E. Rivinus helpfully translated a German account of the species, and K. Swagel x-rayed some FMNH specimens. Earlier drafts of the manuscript were improved by T. D. Price, G. R. Graves, P. Alström, and M. D. Gottfried, Michigan State University Museum.
